ABSTRACT: We propose a method to assess the quality of geometrical scaling in Deep Inelastic Scattering and apply it to the combined HERA data on γ^*p cross-section. Using two different approaches based on Bjorken x binning and binning in γ^*p scattering energy W, we show that geometrical scaling in variable $\tau \sim Q^2 x^{\lambda}$ works well up to Bjorken x's between 0.02 and 0.08. The corresponding value of exponent λ is 0.32 – 0.33.

1 Introduction

Geometrical scaling (GS) introduced in Ref. [1] in the context of low x Deep Inelastic Scattering (DIS) is by now well established phenomenon attributed to the existence of an intermediate energy scale, called saturation scale $Q_s(x)$. Saturation scale is defined as the border line between dense and dilute gluonic systems within a proton (for review see e.g. Refs. [2, 3]). GS has been also observed in DIS on nucleus [4] and in diffraction [5]. Recently it has been shown that GS is also exhibited by the p_T spectra at the LHC [6–8]. Geometrical scaling has a natural explanation within the theory of saturation and the Color Glass Condensate [9–12].

Geometrical scaling takes place if some observable that in principle depends on two independent kinematical variables like Q^2 (or p_T^2) and W (i.e. γ^*p c.m.s. energy) depends only on a specific combination of them, namely on

$$\tau = \frac{Q^2}{Q_s^2(x)} \tag{1.1}$$

called scaling variable. Here

$$x = \frac{Q^2}{Q^2 + W^2 - M_{\rm p}^2} \tag{1.2}$$

is Bjorken x variable, M_p stands for the proton mass, and the saturation scale Q_s takes the following form [1, 13]

$$Q_{\rm s}^2(x) = Q_0^2 \left(\frac{x}{x_0}\right)^{-\lambda}.\tag{1.3}$$

Here Q_0 and x_0 are free parameters which can be fitted to the data within some specific model of DIS, and exponent λ is a dynamical quantity of the order of $\lambda \sim 0.3$. Physical observable that exhibits GS in the case of DIS is $\gamma^* p$ cross-section $\sigma_{\gamma^* p}(x, Q^2) = 4\pi^2 \alpha_{\rm em} F_2(x, Q^2)/Q^2$.

Although many authors, following the original paper by Stasto, Golec-Biernat and Kwecinski [1], have shown that GS is seen in DIS data, until now there was no quantitative, model independent analysis of its applicability domain. Different forms of scaling variable

have been tested in a series of papers [14–16] where the so called Quality Factor (QF) has been defined and used as a tool to assess the quality of geometrical scaling. These authors, however, constrained their analysis only to the domain of small Bjorken x's, x < 0.01 and concentrated on testing the different forms of scaling variable τ . The QF is a new tool for which the quantitative statements, like the one concerning the value of exponent λ for example, are not based on the standard chi-square analysis.

In contrast, in this paper we propose a new numerical criterion for GS which serves as a tool to extract exponent λ by standard χ^2 minimization. We consider $\sigma_{\gamma^*p}(x_i, Q^2)$ for different fixed x_i 's as functions of Q^2 . Geometrical scaling hypothesis means that

$$\sigma_{\gamma^* p}(x_i, Q^2) = \frac{1}{Q_0^2} F(\tau)$$
 (1.4)

where $F(\tau)$ is a universal dimensionless function of τ . Therefore if cross-sections $\sigma_{\gamma^*p}(x_i, Q^2)$ for different x_i are evaluated not in terms of Q^2 but in terms of τ , they should fall on one universal curve (see Figs. 11 and 12 in Sect. 4). This in turn means that if we calculate ratio of cross-sections for different Bjorken x_i 's each expressed in terms of τ , we should get unity independently of τ . This allows to determine power λ by minimizing deviations of these ratios from unity. We can form as many ratios as there are different pairs of x_i 's in overlapping regions of Q^2 (or more precisely of τ). Needless to say that the best values of λ 's extracted from different ratios should coincide within errors.

In an ideal case one would choose the lowest possible x as the reference x_{ref} to calculate the ratios of the cross-sections. Unfortunately there is a strong correlation between Bjorken x's and values of Q^2 measured by HERA [17], and therefore there is no single value of x_i which covers all available values of Q^2 . It turns out that the coverage in space of W (rather than x) and Q^2 is much broader. Therefore in what follows we also study the quality of GS for $\sigma_{\gamma^*p}(W_i, Q^2)$ in bins of W although this requires "rebinning" of the data which are provided by HERA experiments only in bins of (x, Q^2) . There is, however, an advantage of such a procedure, as it is almost identical to the analysis applied to the p_T spectra in pp collisions at the LHC [6, 8].

Since our analysis is sensitive only to the variations of scaling variable τ with x and not to the absolute value of τ , we choose in the following (unless specified otherwise) $Q_0 = 1$ GeV/c and $x_0 = 1$, *i.e.*:

$$\tau = Q^2 x^{\lambda}. (1.5)$$

The absolute value of the saturation scale can be inferred only from some explicit model of DIS at low x. For the purpose of the subsequent analysis we define γ^*p cross-section as

$$\sigma_{\gamma^* p}(x, Q^2) = \frac{F_2(x, Q^2)}{Q^2} \tag{1.6}$$

since all proportionality constants cancel out in the ratios of the cross-sections that are the main tool used to look for geometrical scaling in this paper. The corresponding experimental error is therefore given by

$$\Delta \sigma_{\gamma^* p}^2 = \left(\frac{\Delta F_2}{Q^2}\right)^2 + \left(\frac{F_2}{Q^4} \Delta Q^2\right)^2. \tag{1.7}$$

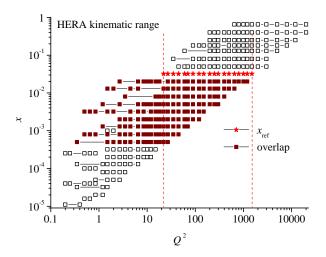

Figure 1. HERA kinematic range in (Q^2, x) plane. It is shown which Bjorken x's (brown full squares) are chosen for given x_{ref} (red stars) to construct ratios of γ^*p cross-sections in scaling variable τ .

For ΔF_2 we use the measured errors of the structure function, for Q^2 we calculate the error from the widths of the Q^2 bins (for details see Ref. [18]).

Our findings can be shortly summarized as follows. Geometrical scaling in variable (1.5) works well up to Bjorken x's between 0.02 and 0.08. The corresponding value of exponent λ is 0.32 - 0.33.

The paper is essentially divided into two parts. In Sect. 2 we discuss GS in terms of Bjorken variable x, whereas in Sect. 3 in terms of γ^*p scattering energy W, in both cases for e^+p scattering. In Sect. 4 we summarize our results and discuss other experiments and also HERA data for e^-p . We also present possible applications of the method proposed in this paper to test other possible forms of scaling variable τ and to investigate scaling of the charm cross-section.

2 Bjorken x binning

Combined study of ZEUS and H1 [17] provides 432 e^+p data points for DIS structure function F_2 in terms of Bjorken x and Q^2 . Here we shall use 348 points with Bjorken x's that have at least 2 points in Q^2 [18]. This choice corresponds to $5.52 \times 10^{-6} \le x \le 0.65$. Since there is a strong correlation between x and Q^2 as far as HERA kinematic range is concerned (see Fig. 1), the analysis outlined in Sect.1 requires some refinement. We apply here the following procedure. First we choose some x_{ref} and consider all Bjorken x_i 's smaller than x_{ref} that have at least two overlapping points in Q^2 (or more precisely in scaling variable τ), as depicted in Fig. 1 (note, however, that when we make the same plot in terms of variable τ rather than Q^2 the overlaps change, usually the number of overlapping points gets smaller). We require that $x_i < x_{\text{ref}}$ because GS holds for small values of Bjorken x and therefore by increasing x_{ref} we will be able to see violations of GS.

For $x_i < x_{\text{ref}}$ the ratios

$$R_{x_i,x_{\text{ref}}}(\lambda;\tau_k) = \frac{\sigma_{\gamma^*p}(x_i,\tau(x_i,Q_k^2;\lambda))}{\sigma_{\gamma^*p}(x_{\text{ref}},\tau(x_{\text{ref}},Q_{k,\text{ref}}^2;\lambda))} \text{ with } \tau_k = \tau(x_i,Q_k^2;\lambda) = \tau(x_{\text{ref}},Q_{k,\text{ref}}^2;\lambda)$$
 (2.1)

are greater than 1 for $\lambda = 0$. By increasing λ one shifts $R_{x_i,x_{\text{ref}}}(\lambda;\tau_k)$ towards unity for all values of τ_k .

Note that $\tau(x_i, Q_k^2; \lambda = 0) = Q_k^2$ and ratios (2.1) are essentially ratios of $\gamma^* p$ cross-sections at overlapping values of Q_k^2 (as in Fig. 1). For $\lambda \neq 0$ points of the same Q^2 but different x's correspond generally to different τ 's. In order to calculate ratios (2.1) at points τ_k corresponding to one fixed x_i , one has to interpolate the reference cross-section $\sigma_{\gamma^* p}(x_{\text{ref}}, \tau(x_{\text{ref}}, Q^2; \lambda))$ to $Q_{k,\text{ref}}^2$ such that $\tau(x_{\text{ref}}, Q_{k,\text{ref}}^2; \lambda) = \tau_k$. Since $\gamma^* p$ cross-sections to a good accuracy lie on straight lines as functions of $\log Q^2$, we apply in the following the linear interpolation in $\log Q^2$. Interpolation errors are neglected.

It is clear than not all available Bjorken x's can be used as $x_{\rm ref}$. If one chooses $x_{\rm ref}$ too small then there are no $x < x_{\rm ref}$ which have at least two points in τ (or Q^2) within $\sigma_{\gamma^*p}(\tau(x_{\rm ref},Q^2))$ domain. It turns out that we can use only $x_{\rm ref} \geq 3.2 \cdot 10^{-5}$.

In order to find optimal exponent λ that minimizes deviations of ratios (2.1) from unity we form the chi-square measure

$$\chi_{x_i, x_{\text{ref}}}^2(\lambda) = \frac{1}{N_{x_i, x_{\text{ref}}} - 1} \sum_{k \in x_i} \frac{(R_{x_i, x_{\text{ref}}}(\lambda; \tau_k) - 1)^2}{\Delta R_{x_i, x_{\text{ref}}}(\lambda; \tau_k)^2}$$
(2.2)

where the sum over k extends over all points of given x_i that have overlap with $x_{\rm ref}$. As already explained above, for $\lambda=0$ this is essentially the sum over all overlapping values of Q_k^2 , for $\lambda\neq 0$ we choose measured points of $\sigma_{\gamma^*p}(\tau(x_i,Q_k^2;\lambda))$ and interpolate the reference cross-section in Q^2 to the point $Q_{k,\rm ref}^2$ such that $\tau(x_{\rm ref},Q_{k,\rm ref}^2;\lambda)=\tau_k$.

Finally, the errors entering formula (2.2) are calculated using

$$\Delta R_{x_i, x_{\text{ref}}}(\lambda; \tau_k)^2 = \left(\frac{\Delta \sigma_{\gamma^* p}(x_i, \tau(x_i, Q_k^2))}{\sigma_{\gamma^* p}(x_{\text{ref}}, \tau(x_{\text{ref}}, Q_{k, \text{ref}}^2))}\right)^2 + \left(\frac{\sigma_{\gamma^* p}(x_i, \tau(x_i, Q_k^2))}{\sigma_{\gamma^* p}(x_{\text{ref}}, \tau(x_{\text{ref}}, Q_{k, \text{ref}}^2))^2} \Delta \sigma_{\gamma^* p}(x_{\text{ref}}, \tau(x_{\text{ref}}, Q_{k, \text{ref}}^2))\right)^2$$
(2.3)

where $\Delta \sigma_{\gamma^* p}(\tau(x, Q^2))$ are experimental errors (or interpolated experimental errors) of $\gamma^* p$ cross-sections (1.7).

By minimizing $\chi^2_{x,x_{\rm ref}}(\lambda)$ of Eq. (2.2) with respect to λ one can compute the "best" value $\lambda_{\min}(x,x_{\rm ref})$ and its error requiring that $(N_{x_i,x_{\rm ref}}-1)\chi^2_{x_i,x_{\rm ref}}(\lambda_{\min})$ changes by 1 around the minimum. In the region where GS is satisfied λ_{\min} should not depend neither on x nor on $x_{\rm ref}$ and $\chi^2_{x,x_{\rm ref}}(\lambda_{\min})$ should be small. In Fig. 2 we plot ratios $R_{x,x_{\rm ref}}(\lambda;\tau_k)$ as functions of τ_k for $\lambda=0$ and $\lambda=\lambda_{\min}$ for some typical values of x and $x_{\rm ref}$. In Fig. 2.a we plot R for both x and $x_{\rm ref}$ small and quite distant, i.e. $x_{\rm ref}/x=10$. Here we expect GS to be satisfied. We see that for $\lambda=0$ ratio R grows with $\tau_k=Q_k^2$ and is of the order $1.5\div 2$. By minimizing $\chi^2_{x,x_{\rm ref}}(\lambda)$ we obtain $\lambda_{\min}=0.306$, which agrees with the expectations. In

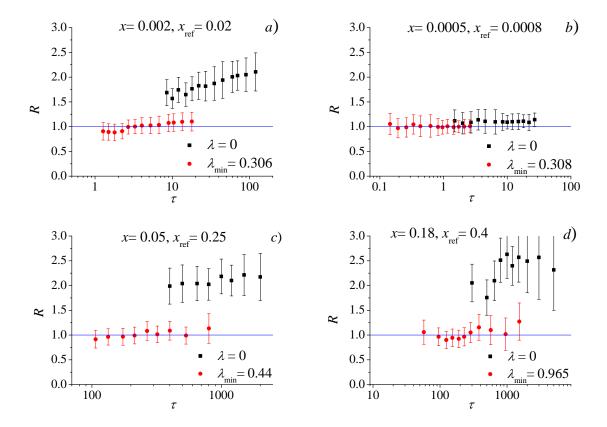

Figure 2. Ratios $R_i(\lambda)$ for $\lambda = 0$ and $\lambda = \lambda_{\min}$ for some typical choices of x and x_{ref} .

Fig. 2.b, both x and $x_{\rm ref}$ are small, however they are not very distant: $x_{\rm ref}/x = 1.6$. We see that already for $\lambda = 0$ ratio $R_{x,x_{\rm ref}}(0;\tau_k)$ is close to 1; we can improve the value of χ^2 by increasing the value of λ to $\lambda_{\rm min} = 0.308$, in fair agreement with the previous case, however one should note that now $\chi^2(\lambda)$ is rather flat. Another example is shown in Fig. 2.c where $x_{\rm ref} = 0.25$ is relatively large and x still quite small, such that $x_{\rm ref}/x = 5$. Here again it is possible to make $R_{x,x_{\rm ref}}(\lambda;\tau_k)$ close to unity, however at the expense of rather large value of $\lambda_{\rm min} = 0.44$. This is a clear sign of violation of the universality of exponent λ , which we consider to be a signature of violation of geometrical scaling. Similarly in Fig. 2.d we show $R_{x,x_{\rm ref}}(\lambda;\tau_k)$ for both x and $x_{\rm ref}$ large and not so close: $x_{\rm ref}/x = 2.22$. Here $\lambda_{\rm min} = 0.965$, which is outrageously large.

The qualitative measure of geometrical scaling is given by the independence of λ_{\min} on Bjorken x and by the value of $\chi^2_{x,x_{\text{ref}}}(\lambda_{\min})$ in the minimum. In Fig. 3 w show contour plots of $\lambda_{\min}(x,x_{\text{ref}})$ and $\chi^2_{x,x_{\text{ref}}}(\lambda_{\min})$ in the (x,x_{ref}) plane. By construction both λ_{\min} and $\chi^2(\lambda_{\min})$ are defined only above the line $x_{\text{ref}} = x$. We see From Fig. 3.a that the stability corner of λ_{\min} (i.e. the region where variations of λ_{\min} are small) extends up to $x_{\text{ref}} \lesssim 0.2$. In the most of this region $0.3 \lesssim \lambda_{\min} \lesssim 0.4$. Similar pattern can be seen in Fig. 3.b where $\chi^2_{x,x_{\text{ref}}}(\lambda_{\min})$ starts rising above $x_{\text{ref}} \simeq 0.35$ with some fluctuation below. From Fig. 3 we can conclude that geometrical scaling holds up to Bjorken x's of the order of 10^{-1} which

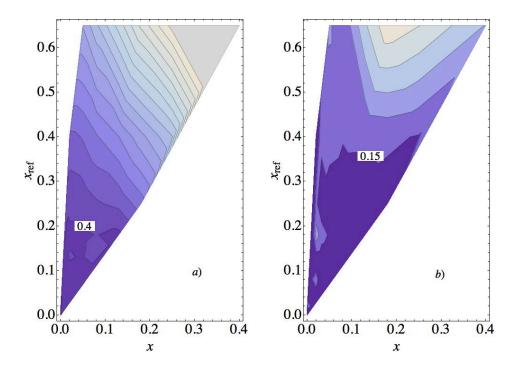

Figure 3. Contour plots of $\lambda_{\min}(x, x_{\text{ref}})$ (a) and $\chi^2_{x, x_{\text{ref}}}(\lambda_{\min})$ (b) in the x, x_{ref} plane. Level lines are spaced by 0.1 for λ and by 0.15 for χ^2 . To set the scale two sample level lines are labeled: 0.4 for λ and 0.15 for χ^2 .

is well above the original expectations. This is nicely illustrated by the three dimensional plot of $\lambda_{\min}(x, x_{\text{ref}})$ in Fig. 4 where the scale of the axes x and x_{ref} is logarithmic. We see rather flat distribution of λ_{\min} up to $x_{\text{ref}} \sim 10^{-1}$ and rapid increase for larger Bjorken x's.

We can now look for possible violation of GS in more quantitative way. In order to eliminate the dependence of $\lambda_{\min}(x, x_{\text{ref}})$ on the value of x, we introduce averages over x (denoted in the following by $\langle \ldots \rangle$) minimizing the following chi-square function:

$$\tilde{\chi}_{x_{\text{ref}}}^{2}(\langle \lambda \rangle) = \frac{1}{N_{x_{\text{ref}}} - 1} \sum_{x < x_{\text{ref}}} \frac{(\lambda_{\min}(x, x_{\text{ref}}) - \langle \lambda \rangle)^{2}}{\Delta \lambda_{\min}(x, x_{\text{ref}})^{2}}$$
(2.4)

which gives the "best" value of λ denoted as $\langle \lambda_{\min}(x_{\text{ref}}) \rangle$. The sum in (2.4) extends over all x's such that $\lambda_{\min}(x, x_{\text{ref}})$ exists (see Fig. 1). $N_{x_{\text{ref}}}$ is the number of terms in (2.4). The results are plotted in Fig. 5 as full (black) squares. Errors $\Delta \langle \lambda_{\min} \rangle$ are calculated from the requirement that $(N_{x_{\text{ref}}} - 1)\tilde{\chi}_{x_{\text{ref}}}^2(\lambda_{\min})$ changes by 1. For some points one can see very large errors; this is due to the small number of possible x's for this particular x_{ref} . On average, however, one can approximate $\langle \lambda_{\min}(x_{\text{ref}}) \rangle$ with a constant value of 0.32 up to $x_{\text{ref}} \sim 0.1$ where the rise of $\langle \lambda_{\min}(x_{\text{ref}}) \rangle$ can be interpreted as violation of geometrical scaling.

Looking at Fig. 5 one may have an impression that on the average $\langle \lambda_{\min}(x_{\text{ref}}) \rangle$ is slightly rising with x. This small rise might be, however, attributed to the dependence of λ on Q^2 through the kinematical correlation between Bjorken x's and Q^2 in the kinematical HERA range (see. Fig. 1). Q^2 dependence of λ has been measured in DIS for very small

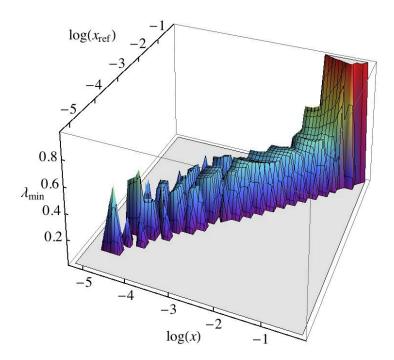

Figure 4. Three dimensional plot of $\lambda_{\min}(x, x_{\text{ref}})$.

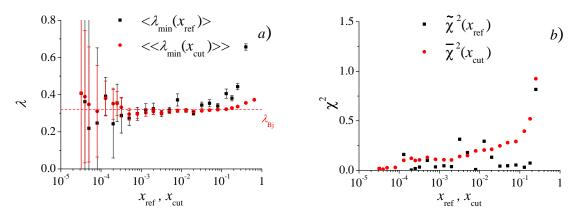

Figure 5. Left: averaged values $\langle \lambda_{\min}(x_{\text{ref}}) \rangle$ (black squares) and $\langle \langle \lambda_{\min}(x_{\text{cut}}) \rangle \rangle$ (red circles); right: $\tilde{\chi}^2_{x_{\text{ref}}}$ (black squares) and $\overline{\chi}^2_{x_{\text{cut}}}$ (red circles) as functions of x_{ref} and x_{cut} , respectively.

x's [19] and has been discussed in the context of the p_T spectra at the LHC [7]. It is theoretically motivated by the corrections due the DGLAP evolution [20, 21]. We shall come back to this possibility in Sect. 4.

To quantify further the hypothesis of geometrical scaling with constant λ we form yet another chi-square function

$$\overline{\chi}_{x_{\text{cut}}}^{2}(\langle\langle\lambda\rangle\rangle) = \frac{1}{N_{x_{\text{cut}}} - 1} \sum_{x_{\text{ref}} < x_{\text{cut}}} \sum_{x < x_{\text{ref}}} \frac{\left(\lambda_{\min}(x, x_{\text{ref}}) - \langle\langle\lambda\rangle\rangle\right)^{2}}{\Delta\lambda_{\min}(x, x_{\text{ref}})^{2}}$$
(2.5)

which we minimize to obtain $\langle \langle \lambda_{\min}(x_{\text{cut}}) \rangle \rangle$.

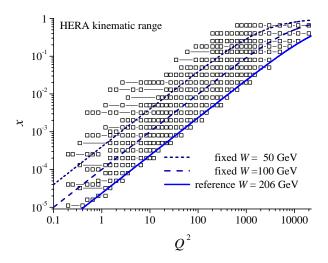

Figure 6. HERA kinematic range in (Q^2, x) plane with several lines of constant W.

The idea behind equation (2.5) is to see how well one can fit $\langle \lambda_{\min}(x_{\text{ref}}) \rangle$ with a constant λ up to $x_{\text{ref}} = x_{\text{cut}}$. Were there any strong violations of GS above some x_0 , one should see a rise of $\langle \langle \lambda_{\min}(x_{\text{cut}}) \rangle \rangle$ once x_{cut} becomes larger than x_0 . As can be seen from Fig. 5, where $\langle \langle \lambda_{\min}(x_{\text{cut}}) \rangle \rangle$ and the corresponding $\overline{\chi}^2_{x_{\text{cut}}}$ are plotted as full (red) circles, no drastic change in $\langle \langle \lambda_{\min}(x_{\text{cut}}) \rangle \rangle$ can be seen, although the slow rise is clearly seen above $x_{\text{cut}} \simeq 0.1$. On the contrary $\overline{\chi}^2_{x_{\text{cut}}}$ rises steeply above $x_{\text{cut}} \simeq 0.1$. Since for large x_{cut} the number of points $N_{x_{\text{cut}}}$ is of the order of a few tens, we can safely assume that violation of GS takes place when $\overline{\chi}^2_{x_{\text{cut}}} \geq 0.3$ which happens precisely around $x_{\text{cut}} \simeq 0.1$. We find therefore that the best value of a constant λ corresponds to $x_{\text{cut}} = 0.08$ which we denote as

$$\lambda_{\rm Bi} = 0.319 \pm 0.005$$
 (2.6)

where subscript "Bj" stands for Bjorken x binning.

Let us finish by a remark on comparison of $\langle\langle\lambda_{\min}(x_{\text{cut}})\rangle\rangle$ with a more "differential" quantity $\langle\lambda_{\min}(x_{\text{ref}})\rangle$ depicted in Fig. 5. Since $\langle\langle\lambda_{\min}(x_{\text{cut}})\rangle\rangle$ is in a sense an average of all $\langle\lambda_{\min}(x_{\text{ref}})\rangle$ for $x_{\text{ref}} < x_{\text{cut}}$, the rapid increase of $\langle\lambda_{\min}(x_{\text{ref}})\rangle$ above $x_{\text{ref}} \simeq 0.1$ is smoothed out due to a long constant tail of $\langle\lambda_{\min}(x_{\text{ref}})\rangle$ for smaller x_{ref} 's. This happens, however, at the expense of the increase of the corresponding χ^2 . Below 0.1 we have that $\langle\lambda_{\min}(x)\rangle \simeq \langle\langle\lambda_{\min}(x)\rangle\rangle$ which further confirms validity of geometrical scaling in this region.

3 Energy binning

Here we are going to repeat analysis of Sect. 2 for the combined HERA data [17], but in bins of (W, Q^2) rather than (x, Q^2) . The reason is that fixed energy points span over much wider common Q^2 range (see Fig. 6) and therefore we do not have to choose different reference points and average over them. Moreover, analysis in terms of W follows exactly the method used to analyze p_T spectra at the LHC [6, 8]. The disadvantage consists in the

W'_{\min} [GeV]	10	13	16.9	22	28.6	37.1	48.3
$W'_{\rm max}$ [GeV]	13	16.9	22	28.6	37.1	48.3	62.7
W [GeV]	11.5	15	19.4	25.3	32.8	42.7	55.5
Number of points	6	3	13	22	22	32	33
W'_{\min} [GeV]	62.7	81.6	106	137.9	179.2	233	
$W'_{\rm max} [{\rm GeV}]$	81.6	106	137.9	179.2	233	302.9	
$W [\mathrm{GeV}]$	72.2	93.8	122	158.5	206.1	267.9	
Number of points	40	40	42	43	44	7	

Table 1. Energy bins and energies assigned to them. Number of points in different bins is also displayed (these are values for e^+p data).

fact that HERA points are not organized in the energy bins, therefore we have to "rebin" them using formula (1.2). This leads to the loss of statistics. Indeed, instead of 432 points (see Sect. 2) we shall use here 347 e^+p data points. Furthermore some ambiguities arise, such as the choice of the bin size, the need to recalculate Bjorken x and others discussed in detail in Ref. [18]. In what follows we shall use logarithmic binning with step 1.3 – every consecutive W is 1.3 times larger than preceding one (in Ref. [18] different binnings have been also considered without any major change of the results). We define value of energy W as the mean of two limiting values W'_{\min} and W'_{\max} between which it lies (see Table 1).

In what follows we use $W_{\rm ref} = 206$ GeV because it gives the widest range of τ values and is one of the biggest energies that we have at our disposal (GS is expected to be present at large energies), and it has the largest number of points in Q^2 . In Ref. [18] different choices of $W_{\rm ref}$ have been also analyzed with essentially the same conclusions.

Similarly to the case of x-binning we shall construct ratios of γ^*p cross-sections at different W's as functions of τ . In general τ values for $W_{\rm ref}$ and W are different so we need to interpolate the reference cross-section to the value of $Q_{\rm ref}^2$ which corresponds to the τ value needed to calculate the ratio. Here we follow closely the method of Sect.2 using linear interpolation in $\log Q^2$ and neglecting interpolation errors.

Now for every point with energy W_i (note that $W_i < W_{\text{ref}}$) we define a ratio (k labels points with energy W_i but of different Q^2):

$$R_{W_i,W_{\text{ref}}}(\lambda;\tau_k) := \frac{\sigma_{\gamma^*p}(W_{\text{ref}},\tau(W_{\text{ref}},Q_{k,\text{ref}};\lambda))}{\sigma_{\gamma^*p}(\tau(W_i,Q_k;\lambda))} \text{ with } \tau_k = \tau(W_i,Q_k^2;\lambda) = \tau(W_{\text{ref}},Q_{k,\text{ref}}^2;\lambda).$$
(3.1)

Uncertainty of ratio $R_{W_i,W_{\text{ref}}}(\lambda;\tau_k)$ is given by:

$$\Delta R_{W_{i},W_{\text{ref}}}(\lambda;\tau_{k})^{2} = \left(\frac{\Delta \sigma_{\gamma^{*}p}(W_{\text{ref}},\tau(W_{\text{ref}},Q_{k,\text{ref}}^{2}))}{\sigma_{\gamma^{*}p}(W_{i},\tau(W_{i},Q_{k}^{2}))}\right)^{2} + \left(\frac{\sigma_{\gamma^{*}p}(W_{\text{ref}},\tau(W_{\text{ref}},Q_{k,\text{ref}}^{2}))^{2}}{\sigma_{\gamma^{*}p}(W_{i},\tau(W_{i},Q_{k}^{2}))}\Delta \sigma_{\gamma^{*}p}(W_{i},\tau(W_{i},Q_{k}^{2}))\right)^{2}.$$
(3.2)

Since we have fixed $W_{\text{ref}} = 206 \text{ GeV}$, in what follows we shall omit subscript W_{ref} .

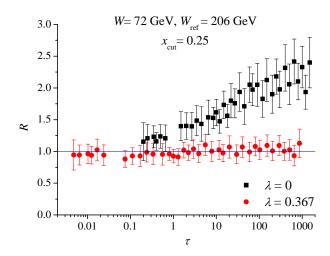

Figure 7. Ratios $R_{72}(\lambda)$ for $\lambda = 0$ and $\lambda = \lambda_{\min} = 0.367$ both with $x_{\text{cut}} = 0.25$.

In Fig. 7 we show as an example R_{72} plotted for $\lambda = 0$ and $\lambda = 0.367$. We see that R_{72} decreases several times when we use scaling variable rather than Q^2 . This is generic feature which we employ to look for geometrical scaling.

Our aim is to find such λ for given energy $W_i < W_{\text{ref}}$ that deviations $R_{W_i}(\lambda; \tau_k) - 1$ are minimal. Taking into account uncertainties ΔR_W we define the chi-square function:

$$\chi_{W_i}^2(x_{\text{cut}}; \lambda) = \frac{1}{N_{W_i, x_{\text{cut}}} - 1} \sum_{k \in W_i; x \le x_{\text{cut}}} \frac{(R_{W_i}(\lambda; \tau_k) - 1)^2}{\Delta R_{W_i}(\lambda; \tau_k)^2}$$
(3.3)

where $k \in W_i$; $x \le x_{\text{cut}}$ means that we sum over points corresponding to given energy W_i and values of x that are not larger than x_{cut} . The reason to introduce a cut-off on Bjorken x is to look for violations of GS once we get into the region of large x's.

We will search $\lambda_{\min}(W_i, x_{\text{cut}})$ which minimizes $\chi^2_{W_i}$ for given W_i and x_{cut} . Uncertainty of λ_{\min} is estimated by requiring that $(N_{W_i,x_{\text{cut}}}-1)\chi^2_{W_i}(x_{\text{cut}};\lambda)$ changes by 1 when λ is varied around the minimum. The results for 12 different energy bins are plotted in Fig. 8. One can see that in each W_i bin $\lambda_{\min}(x_{\text{cut}})$ can be approximated by a constant, although for lower energies a slight increase for $x_{\text{cut}} \geq 0.1$ is present. Large error bars for higher energies are due to the fact that $\chi^2_{W_i}$ gets flatter once W_i is close to W_{ref} . Since at low energies there are no points of low $x \leq 10^{-3}$, in what follows we shall restrict the energy range to $W_i \geq 25$ GeV. We shall also skip the highest energy bin of W = 268 GeV since it contains only 7 points and the corresponding λ_{\min} has very large errors (see Fig. 8) exhibiting different behavior with x_{cut} than for other energies, which suggests some systematic binning effect that we do not have under control. Therefore the final number of data points used in the analysis in this Section is further reduced to 318. In Fig. 9 we plot the corresponding values of $\chi^2_{W_i}$. One can see that up to $x_{\text{cut}} \simeq 0.1$ the $\chi^2_{W_i}$'s are below 0.2, and the rapid growth is seen for $x_{\text{cut}} > 0.1$. Before we can conclude that GS is well satisfied for Bjorken x's up to 0.1, we have to check whether the corresponding $\lambda_{\min}(W_i)$ are energy independent. For

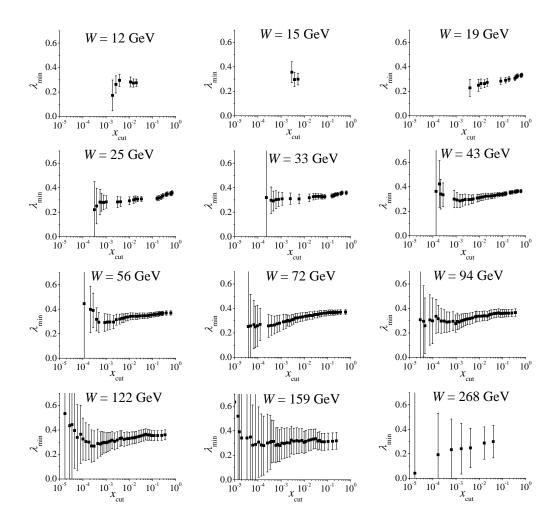

Figure 8. Exponent λ_{\min} as a function of x_{cut} for all energies $W \neq W_{\text{ref}} = 206 \text{ GeV}$.

very small x_{cut} 's in turn we have small numbers of points in (3.3) and the calculated values of $\chi_{W_c}^2$ are statistically not reliable.

Finally, in order to get rid of the energy dependence we define yet another chi-square function

$$\tilde{\chi}^2(x_{\text{cut}}; \lambda) = \frac{1}{N_{x_{\text{cut}}} - 1} \sum_i \frac{(\lambda_{\min}(W_i, x_{\text{cut}}) - \lambda)^2}{\Delta \lambda_{\min}(W_i, x_{\text{cut}})^2}$$
(3.4)

where the sum goes over eight energies $W_i = 25, 33, \ldots, 159$ GeV. By minimizing (3.4) with respect to λ we obtain the best value of $\lambda_{\min}(W_i, x_{\text{cut}})$ averaged over all energies which we denote by $\lambda_{\text{ave}}(x_{\text{cut}})$. The error of λ_{ave} is calculated again by demanding that $(N_{x_{\text{cut}}} - 1)\tilde{\chi}^2(x_{\text{cut}}; \lambda)$ changes by 1 when λ is varied around λ_{ave} . Both $\lambda_{\text{ave}}(x_{\text{cut}})$ and the corresponding $\tilde{\chi}^2$ are plotted as functions of x_{cut} in Fig. 10. We see that $\lambda_{\text{ave}}(x_{\text{cut}})$ is rather flat; large errors for small x_{cut} are due to the small number of points with small x's. Looking at $\lambda_{\text{ave}}(x_{\text{cut}})$ one does not see any dramatic change for $x_{\text{cut}} \to 1$. On the other hand the value of $\tilde{\chi}^2$ starts rapidly growing at $x_{\text{cut}} \simeq 0.02$. We can therefore conclude that

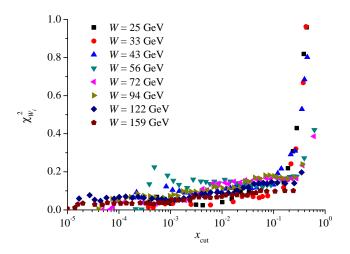

Figure 9. Plot of $\chi_{W_i}^2$ for different energies in function of x_{cut} .

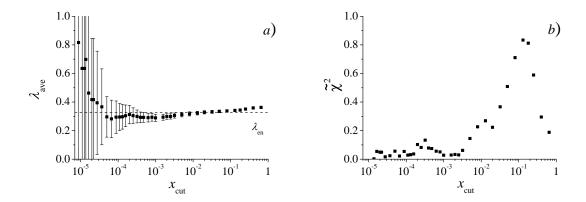

Figure 10. Exponent λ_{\min} averaged over energies (denoted as λ_{ave}) as a function of x_{cut} and the corresponding $\tilde{\chi}^2$.

GS works well up to Bjorken x's of the order of 0.02 with

$$\lambda_{\text{en}} = \lambda_{\text{ave}}(x_{\text{cut}} = 0.02) = 0.328 \pm 0.011.$$
 (3.5)

where subscript "en" stands for energy binning.

4 Summary and outlook

In the present paper we have performed quantitative, model independent analysis of the accuracy and the applicability domain of geometrical scaling in deep inelastic e^+p scattering. To this end we have chosen the most recent compilation of the HERA data based on common analysis of ZEUS and H1 experiments [17]. We have tested the standard form of geometrical scaling [1, 13] given by the form of the scaling variable τ (1.5), assuming the constant value of the exponent λ . In order to quantify the quality of GS we have proposed

two different approaches. In the first approach we have computed ratios of cross-sections F_2/Q^2 for two different Bjorken x's, denoted as x and $x_{\rm ref}$, as functions of the scaling variable τ ; such ratios should be equal to unity if GS is present. This allowed us to extract the best value of the exponent λ , which we called $\lambda_{\min}(x, x_{\rm ref})$. In the region where GS is present $\lambda_{\min}(x, x_{\rm ref})$ should not depend on x and $x_{\rm ref}$, and moreover the corresponding χ^2 should be small. In the second approach we have repeated essentially the same calculation but for γ^*p cross-sections treated as functions of the scattering energy W rather than x. This procedure is analogous to the one applied to the $p_{\rm T}$ spectra at the LHC. It requires, however, "rebinning" of the data, which reduces the statistics and introduces uncontrollable errors, for example the uncertainty of x, and also in principle some uncontrollable dependence on the choice of W bins. Nevertheless, since γ^*p cross-sections for all available energies overlap in Q^2 (or τ) nearly over whole kinematical range (which is not the case for the x binning, see Figs. 1 and 6), the analysis is much more straightforward than in the case of the Bjorken x binning.

Despite the differences between the Bjorken x binning and the energy binning the results in both cases are consistent and to some extent surprising. By averaging $\lambda_{\min}(x, x_{\text{ref}})$ or $\lambda_{\min}(W, W_{\text{ref}})$ over the allowed regions of x or W respectively, and by inspecting the corresponding χ^2 values, as described in detail in Sects. 2 and 3, we have established that geometrical scaling holds up to relatively large x's of the order of 0.08 for the Bjorken x binning and 0.02 for the energy binning. The resulting exponents λ given by Eqs. (2.6) and (3.5) agree within errors and are consistent with previous estimates and model calculations

$$\lambda = 0.32 \div 0.33. \tag{4.1}$$

These results are suggestively illustrated in Figs. 11 and 12 where we plot γ^*p cross-sections for both types of binning used in this paper as functions of Q^2 and the scaling variable τ (with $Q_0 = 1 \text{ GeV}/c$ and $x_0 = 10^{-3}$ in Eq.(1.3)). One can see that in both cases the cross-sections fall on one universal curve – a clear sign of geometrical scaling. Some deviations of GS can be seen in the lower right end of the plots. These points, however, correspond to large x's (due to the kinematical correlation of the HERA phase space, see Figs. 1, 6), and therefore should not exhibit geometrical scaling.

The analysis performed here is essentially identical to the one presented in in Ref. [18] with one important difference. Here, when interpolating γ^*p cross-section in Q^2 we used linear interpolation in $\log Q^2$, rather than in Q^2 . The latter interpolation introduces large errors which were neglected in [18]. This resulted in somewhat different values of the exponent λ . Qualitative picture, however, remains unchanged.

One of the questions addressed in [18] was possible dependence of λ on Q^2 . Applying the same method of dividing γ^*p cross-sections of different Bjorken x's (or scattering energies W) we have been looking for the best exponent λ which, in this case however, depended on Q^2 . Instead of having one parameter λ we had therefore a number of parameters λ_k where k runs over all Q^2 bins. By minimizing χ^2 analogous to (2.2) or (3.3) we did not observe any visible dependence of λ on Q^2 . This is most probably due to the fact that the corresponding χ^2 functions are very flat and one can easily fall into some accidental minimum. We therefore conclude that with the present experimental accuracy

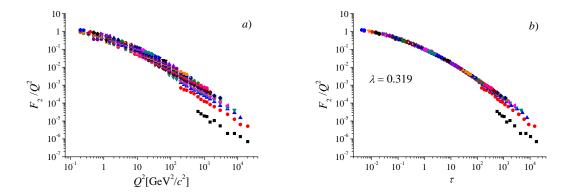

Figure 11. Geometrical scaling for the Bjorken binning. Left: $\gamma^* p$ cross-sections F_2/Q^2 as functions of Q^2 for fixed x. Different points correspond to different Bjorken x's. Right: the same but in function of scaling variable τ for $\lambda = 0.319$. Points in the right end of the plot correspond to large x's (due to kinematical correlation of the HERA phase space), and therefore show explicitly violation of geometrical scaling.

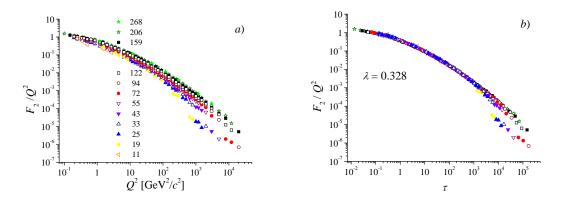

Figure 12. Geometrical scaling for the energy binning. Left: γ^*p cross-sections F_2/Q^2 as functions of Q^2 for fixed W's. Right: the same but in function of scaling variable τ for $\lambda = 0.328$. Points in the right end of the plot correspond to large x's and mostly small energies (due to kinematical correlation of the HERA phase space), and therefore show explicitly violation of geometrical scaling.

we have been unable to find Q^2 dependence of λ in a model independent way. It seems that in this case one has to assume some Ansatz for $\lambda(Q^2)$ depending on a few variational parameters which can be found using the methods described in this paper. Universality of these parameters would then constitute a criterion for Q^2 dependence of λ .

We have also analyzed separately γ^*p cross-section for e^-p scattering. The e^-p data cover narrower range of Q^2 values and therefore the smallest $x_{\min} = 0.002$ is rather large as far as GS is concerned. Nevertheless the results for e^-p and e^+p scattering restricted to the same kinematical region are very similar except for some small systematic shift of the exponent λ towards higher values in the e^-p case [18].

Natural question concerning other deep inelastic scattering experiments arises. Here

we have μp scattering experiments: EMC [22] with the smallest Bjorken $x_{\min} = 0.0175$, BCMDS [23] ($x_{\min} = 0.07$), NMC [24] ($x_{\min} = 0.008$), E665 [25] ($x_{\min} = 8 \times 10^{-4}$) and SLAC e^-p experiment [26] ($x_{\min} = 0.063$). Let us remind here that the lowest Bjorken x for the combined HERA analysis is by far the smallest: $x_{\min} = 5.52 \times 10^{-6}$. This alone singles out HERA data as the best experimental sample to look for geometrical scaling. Since, basing on our experience with e^-p data, we expect some possible systematic differences due to the projectile used in different experiments, we have analyzed – following the steps of Sect. 2 – each of these experiments separately. We have observed, indeed, rather large systematic differences between various experiments in the overlapping region of Bjorken x's (i.e. for large x) as far as $\langle \lambda_{\min} \rangle$ and $\langle \langle \lambda_{\min} \rangle \rangle$ are concerned. However, due to large errors of $\langle \lambda_{\min} \rangle$ and $\langle \langle \lambda_{\min} \rangle \rangle$ it is difficult to quantify the amount of violation of GS in these experiments. As far as E665 data is concerned, we could see qualitative agreement with the combined HERA data, although E665 data suffer from very large errors for $\langle \lambda_{\min} \rangle$ and $\langle \langle \lambda_{\min} \rangle \rangle$. More detailed analysis and comparison of DIS experiments [22–26] with the combined HERA data [17] will be presented elsewhere.

It is worthwhile mentioning that our results for the best value of the exponent λ are in a very good agreement with the quality factor analysis of Ref. [14] $\lambda = 0.321 \pm 0.056$ and with later analysis of the combined HERA data only [16] $\lambda = 0.31$. In both cases, however, the analysis was constrained to x < 0.01 with some additional cuts on Q^2 and y which have not been applied in our study.

Obviously our method can be applied to test different forms of scaling variable τ which follow from the QCD non-linear evolution equations [14–16]. Finally, the question of the possible existence of geometrical scaling for the charm cross-section F_2^c/Q^2 [15, 27] where the charm quark mass plays an important role may also be studied with the method proposed in this paper.

Acknowledgements

MP would like to thank Robi Peschanski for discussion and for drawing his attention to the quality factor studies of geometrical scaling and Gosta Gustafson for pointing out the problem of the charm F_2^c studied in Ref. [27]. This work was supported by the Polish NCN grant 2011/01/B/ST2/00492.
